Abstract
A key challenge in the design of multi-sensor systems is the efficient allocation of scarce resources such as bandwidth, CPU cycles, and energy, leading to the dynamic sensor selection problem in which a subset of the available sensors must be selected at each timestep. While partially observable Markov decision processes (POMDPs) provide a natural decision-theoretic model for this problem, the computational cost of POMDP planning grows exponentially in the number of sensors, making it feasible only for small problems. We propose a new POMDP planning method that uses greedy maximization to greatly improve scalability in the number of sensors. We show that, under certain conditions, the value function of a dynamic sensor selection POMDP is submodular and use this result to bound the error introduced by performing greedy maximization. Experimental results on a real-world dataset from a multi-camera tracking system in a shopping mall show it achieves similar performance to existing methods but incurs only a fraction of the computational cost, leading to much better scalability in the number of cameras.

Introduction
Multi-sensor systems are becoming increasingly prevalent in a wide range of settings. For example, multi-camera systems are now routinely used for security, surveillance, and tracking. A key challenge in the design of such systems is the efficient allocation of scarce resources such as the bandwidth required to communicate the collected data to a central server, the CPU cycles required to process that data, and the energy costs of the entire system. This gives rise to the dynamic sensor selection problem (Spaan and Lima 2009; Kreucher, Kastella, and Hero 2005; Williams, Fisher, and Willsky 2007): selecting, based on the system’s current uncertainty about its environment, \( K \) of the \( N \) available sensors to use at each timestep, where \( K \) is the maximum number of sensors allowed given the resource constraints.

When the state of the environment is static, a myopic approach that always selects the sensors that maximize the immediate expected reduction in uncertainty is typically sufficient. However, when that state changes over time, a non-myopic approach that reasons about the long-term effects of the sensor selection performed at each step can perform better. A natural decision-theoretic model for such an approach is the partially observable Markov decision process (POMDP) (Aström 1965; Smallwood and Sondik 1973; Kaelbling, Littman, and Cassandra 1998) in which actions specify different subsets of sensors.

In a typical POMDP, reducing uncertainty about the state is only a means to an end. For example, in a robot control task, the robot aims to determine its current location so it can more easily reach its goal. However, dynamic sensor selection is a type of active perception problem (Spaan 2008; Spaan and Lima 2009), which can be seen as a subclass of POMDPs in which reducing uncertainty is an end in itself. For example, a surveillance system’s goal is typically just to ascertain the state of its environment, not use that knowledge to achieve another goal. While perception is arguably always performed to aid decision-making, in an active perception problem that decision is made by another agent, e.g., a human, not modeled by the POMDP.

Although POMDPs are computationally expensive to solve, approximate methods such as point-based planners (Pineau, Gordon, and Thrun 2006; Araya et al. 2010) have made it practical to solve POMDPs with large state spaces. However, dynamic sensor selection poses a different challenge: as the number of sensors \( N \) grows, the size of the action space \( \binom{N}{K} \) grows exponentially. Consequently, as the number of sensors grows, solving the POMDP even approximately quickly becomes infeasible with existing methods.

In this paper, we propose a new point-based planning method for dynamic sensor selection that scales much better with the number of sensors. The main idea is to replace maximization with greedy maximization (Nemhauser, Wolsey, and Fisher 1978; Golovin and Krause 2011; Krause and Golovin 2014) in which a subset of sensors is constructed by iteratively adding the sensor that gives the largest marginal increase in value. Doing so avoids iterating over the entire action space, yielding enormous computational savings.

In addition, we present theoretical results bounding the error in the value functions computed by this method. Our core result is that, under certain conditions including submodularity (Krause and Golovin 2014; Nemhauser, Wolsey, and Fisher 1978), the value function computed using POMDP backups based on greedy maximization has bounded error. We also show that such conditions are met, or approximately met, if reward is defined using negative belief entropy or an
The value function is given by the Bellman equation

\[ V^\pi_t(b) = \rho(b, a_\pi) + \gamma \sum_{z \in \Omega} \Pr(z|a_\pi, b)V^\pi_{t-1}(b^z, a). \]  

The action-value function \( Q^\pi_t(b, a) \) is the value of taking action \( a \) and following \( \pi \) thereafter:

\[ Q^\pi_t(b, a) = \rho(b, a) + \gamma \sum_{z \in \Omega} \Pr(z|a, b)V^\pi_{t-1}(b^z, a). \]

The optimal value function \( V^\pi_t(b) \) is given by the Bellman optimality equation:

\[ V^\pi_t(b) = \max_a Q^\pi_t(b, a) \]

\[ = \max_a [\rho(b, a) + \gamma \sum_{z \in \Omega} \Pr(z|a, b)V^\pi_{t-1}(b^z, a)]. \]

We can also define the Bellman optimality operator \( \mathfrak{B}^* \):

\[ (\mathfrak{B}^* V_{t-1})(b) = \max_a [\rho(b, a) + \gamma \sum_{z \in \Omega} \Pr(z|a, b)V_{t-1}(b^z, a)], \]

and write (4) as:

\[ V^\pi_t(b) = (\mathfrak{B}^* V^\pi_{t-1})(b). \]

An important consequence of (1) is that \( V^\pi_t \) is piecewise linear and convex (PWLC). This property, which is exploited by most POMDP planners, allows \( V^\pi_t \) to be represented by a set of vectors: \( \Gamma_t = \{ \alpha_1, \alpha_2, \ldots, \alpha_m \} \), where each \( \alpha \)-vector is an \( |S| \)-dimensional hyperplane representing \( V^\pi_t(b) \) in a bounded region of belief space. The value function can then be written as

\[ V^\pi_t(b) = \max_{\alpha} \sum_b \rho(b, a) \alpha_i(b). \]

Dynamic Sensor Selection POMDPs

We model the dynamic sensor selection problem as a POMDP in which the agent must choose a subset of available sensors at each timestep. We assume that all selected sensors must be chosen simultaneously, i.e., it is not possible to compute time consuming, e.g., because it requires applying expensive computer vision algorithms, and thus all observations must be generated in parallel. Formally, a dynamic sensor selection POMDP has the following components:

- Actions \( a = \{a_1 \ldots a_N\} \) are modeled as vectors of \( N \) binary action features, each of which specifies whether a given sensor is selected or not (assuming \( N \) sensors). For each \( a \), we also define its set equivalent \( a = \{i : a_i = 1\} \), i.e., the set of indices of the selected sensors. Due to the resource constraints, the set of all actions \( A = \{a : |a| \leq K\} \) contains only sensor subsets of size \( K \) or less. \( A^+ = \{1, \ldots, N\} \) indicates the set of all sensors.

- Observations \( z = \{z_1 \ldots z_N\} \) are modeled as vectors of \( N \) observation features, each of which specifies the sensor reading obtained by the given sensor. If sensor \( i \) is not selected, then \( z_i = 0 \). The set equivalent of \( z \) is \( \tilde{z} = \{z_i : z_i \neq 0\} \). To prevent ambiguity about which sensor generated which observation in \( \tilde{z} \), we assume that, for all \( i \) and \( j \), the domains of \( z_i \) and \( z_j \) share only 0.

- The transition function \( T(s', s) = \Pr(s'|s, a) \) is independent of \( a \) because the agent’s role is purely observational.

- The belief-based reward \( \rho(b, \tilde{z}) \) is also independent of \( a \) and is typically some measure of the agent’s uncertainty. A natural choice is the negative entropy of the belief:

\[ \rho(b) = -H_b(s) = \sum_s \Pr(s|b) \log(\Pr(s|b)). \]

This definition destroys the PWLC property. Instead, we approximate \( -H_b(s) \) using a set of vectors \( \Gamma^\rho = \{\alpha_1^\rho, \ldots, \alpha_m^\rho\} \), each of which is a tangent to \( -H_b(s) \), as suggested by (Araya et al. 2010). Figure 1 shows the tangents for an example \( \Gamma^\rho \) for a two-state POMDP. Because these tangents provide a PWLC approximation to belief entropy, the value function is also PWLC and can thus be computed using standard solvers.

Point-Based Value Iteration

Exact POMDP planners (Smallwood and Sondik 1973; Monahan 1982; Lovejoy 1991; Kaelbling, Littman, and Cassandra 1998) compute the optimal \( \Gamma^\pi \)-sets for all possible belief points. However, this approach is intractable for all but small POMDPs. By contrast, point-based value iteration (PBVI) (Pineau, Gordon, and Thrun 2006) achieves much better scalability by computing the \( \Gamma^\pi \)-sets only for a set of sampled beliefs \( B \), yielding an approximation of \( V^\pi_t \).

At each iteration, PBVI computes \( \Gamma^\pi_t \) given \( \Gamma^\pi_{t-1} \) as follows. The first step is to generate intermediate \( \Gamma^\pi_{t,a} \)-sets for all \( a \in A \) and \( \pi \in \Omega^a \): \( \Gamma^\pi_{t,a} = \{\alpha^\pi,a : \alpha \in \Gamma_{t-1}\} \), where

\[ \alpha^\pi,a(s) = \gamma \sum_{s' \in S} T(s, s') O(s', a, z) \alpha(s'). \]
by iteratively adding elements of the argmax variant, which constructs a subset (Nemhauser, Wolsey, and Fisher 1978), an algorithm that better scalability in greedy PBVI (Pineau, Gordon, and Thrun 2006). For all beliefs, rely on pruning operators instead of argmax. Since the complexity of greedy-argmax is only $O(|N||K|)$, this yields a complexity for greedy PBVI of only $O(|S||N||K||\Gamma_{t-1}||\Omega||B|)$.

Note that, since the point of greedy maximization is not to iterate over $A$, it is crucial that our implementation does not first compute $\alpha_{a,b}$ and $Q(b,a)$ for all $a \in A$, as this would already introduce an $|A| = \binom{N}{K}$ term into the complexity. Instead, $\alpha_{a,b}$ and $Q(b,a)$ are computed on the fly only for the $a$'s considered by greedy-argmax. The computational complexity of one iteration of PBVI is $\mathcal{O}(Q)$.

Analysis: Bounds given Submodularity

In this section, we present our core theoretical result, which shows that, under certain conditions, the most important of which is submodularity, the error in the value function computed by backups based on greedy maximization is bounded. Later sections discuss when reward based on negative belief entropy or an approximation thereof meets those conditions.

Submodularity is a property of set functions that corresponds to diminishing returns, i.e., adding an element to a set increases the value of the set function by a smaller or equal amount than adding that same element to a subset. In our notation, this is formalized as follows. The set function $Q^*_t(b,a)$ is submodular in $a$, if for every $a_M \subseteq a_N \subseteq A^+$ and $a_e \in A^+ \setminus a_N$,

$$\Delta_{Q^*_t}(a_e|a_M) \geq \Delta_{Q^*_t}(a_e|a_N),$$

where $\Delta_{Q^*_t}(a_e|a) = Q^*_t(b,a \cup \{a_e\}) - Q^*_t(b,a)$ is the discrete derivative of $Q^*_t(b,a)$. Equivalently, $Q^*_t(b,a)$ is submodular if for every $a_M, a_N \subseteq A^+$,

$$Q^*_t(b,a_M \cup a_N) + Q^*_t(b,a_M \cap a_N) \leq Q^*_t(b,a_M) + Q^*_t(b,a_N).$$

Submodularity is an important property because of the following result by Nemhauser, Wolsey, and Fisher (1978):

**Theorem 1.** If $Q^*_t(b,a)$ is non-negative, monotone and submodular in $a$, then for all $b$,

$$Q^*_t(b,a^G) \geq (1 - 1^{-1})Q^*_t(b,a^*),$$

where $G = \text{greedy-argmax}(Q^*_t(b,\cdot), A^+, K)$ and $a^* = \arg \max_{a \in A} Q^*_t(b,a)$.

However, Theorem 1 gives a bound only for a single application of greedy-argmax, not for applying it within each
backup, as greedy PBVI does. In this section, we establish such a bound. Let the greedy Bellman operator $\mathfrak{B}^G$ be:

$$ (\mathfrak{B}^GV_{t-1})(b) = \max_a [\rho(b, a) + \gamma \sum_{z \in \Omega}Pr(z|a, b)V_{t-1}(b^z, a)], $$

where $\max_a$ refers to greedy maximization. This immediately implies the following corollary to Theorem 1:

**Corollary 1.** Given any policy $\pi$, if $Q^\pi_t(b, a)$ is non-negative, monotone, and submodular in $a$, then for all $b$,

$$ (\mathfrak{B}^GV^\pi_{t-1})(b) \geq (1 - e^{-1})(\mathfrak{B}^ GV^\pi_{t-1})(b). \quad (12) $$

**Proof.** From Theorem 1 since $(\mathfrak{B}^ GV^\pi_{t-1})(b) = Q^\pi_t(b, a^G)$ and $(\mathfrak{B}^ GV^\pi_{t-1})(b) = Q^\pi_t(b, a^*)$.

In addition, we can prove that the error in the value function remains bounded after application of $\mathfrak{B}^G$.

**Lemma 1.** If for all $b$, $\rho(b) \geq 0$,

$$ V^\pi_t(b) \geq (1 - e^{-1})V^*_{t-1}(b), \quad (13) $$

and $Q^\pi_t(b, a)$ is non-negative, monotone, and submodular in $a$, then, for $\epsilon \in [0, 1]$,

$$ (\mathfrak{B}^GV^\pi_{t-1})(b) \geq (1 - e^{-1})(1 - \epsilon)(\mathfrak{B}^ GV^\pi_{t+1})(b). \quad (14) $$

**Proof.** Starting from (13) and, for a given $a$, on both sides adding $\gamma \geq 0$, taking the expectation over $z$, and adding $\rho(b)$ (since $\rho(b) \geq 0$ and $e \leq 1$):

$$ \rho(b) + \gamma \mathbb{E}_{z|b,a}[V^\pi_{t+1}(b^z, a)] \geq (1 - \epsilon)(\rho(b) + \gamma \mathbb{E}_{z|b,a}[V^*_{t+1}(b^z, a)]). $$

From the definition of $Q^\pi_{t+1}$, we thus have:

$$ Q^\pi_{t+1}(b, a) \geq (1 - \epsilon)Q^\pi_{t+1}(b, a) \quad \forall a. \quad (15) $$

From Theorem 1, we know

$$ Q^\pi_{t+1}(b, a^G) \geq (1 - e^{-1})Q^\pi_{t+1}(b, a^*), \quad (16) $$

where $a^G = \text{greedy-argmax}(Q^\pi_t(b, \cdot), A^+, K)$ and $a^* = \text{arg max } a Q^\pi_{t+1}(b, a)$. Since $Q^\pi_{t+1}(b, a^*) \geq Q^\pi_{t+1}(b, a)$ for any $a$,

$$ Q^\pi_{t+1}(b, a^G) \geq (1 - e^{-1})Q^\pi_{t+1}(b, a^G), \quad (17) $$

where $a^G = \text{greedy-argmax}(Q^\pi_t(b, \cdot), A^+, K)$. Finally, (15) implies that $Q^\pi_{t+1}(b, a^G) \geq (1 - e^{-1})Q^\pi_{t+1}(b, a^G)$.

Next, we define the greedy Bellman equation: $V_{t}^G(b) = (\mathfrak{B}^ GV^G_{t-1})(b)$, where $V^G_{t} = \rho(b)$. Note that $V^G_{t}$ is the true value function obtained by greedy maximization, without any point-based approximations. Using Corollary 1 and Lemma 1, we can bound the error of $V^G_{t}$ with respect to $V^*$. 

**Theorem 2.** If for all policies $\pi$, $Q^\pi_t(b, a)$ is non-negative, monotone and submodular in $a$, then for all $b$,

$$ V^G_{t-1}(b) \geq (1 - e^{-1})2tV^*_{t-1}(b), \quad (18) $$

**Proof.** By induction on $t$. The base case, $t = 0$, holds because $V^G_{0}(b) = \rho(b) = V^*_0(b)$.

In the inductive step, for all $b$, we assume that

$$ V^G_{t-1}(b) \geq (1 - e^{-1})2tV^*_t(b), \quad (19) $$

and must show that

$$ V^G_{t}(b) \geq (1 - e^{-1})2tV^*_t(b). \quad (20) $$

Applying Lemma 1 with $V^G_{t} = V^G_{t-1}$ and $(1 - e^{-1})2t = 2(1 - e^{-1})2t-2$ to (19):

$$ (\mathfrak{B}^ GV^G_{t-1})(b) \geq (1 - e^{-1})2(1 - e^{-1})V^G_{t-1}(b) $$

$$ V^G_t(b) \geq (1 - e^{-1})2tV^*_t(b). \quad (21) $$

Now applying Corollary 1 with $V^*_{t-1} = V^G_{t-1}$:

$$ V^G_t(b) \geq (1 - e^{-1})2t-1(1 - e^{-1})V^*_{t-1}(b) $$

$$ V^G_t(b) \geq (1 - e^{-1})2tV^*_t(b). \quad (22) $$

**Analysis: Submodularity under Belief Entropy**

In this section, as we show that, if the belief-based reward is negative entropy, i.e., $\rho(b) = -H_b(s)$, then under certain conditions $Q^G_t(b, a)$ is submodular, non-negative and monotone, as required by Theorem 2. We start by observing that:

$$ Q^G_t(b, a) = \rho(b) + \sum_{k=1}^K G_k^G(b^k, a^k), $$

where $G_k^G(b^k, a^k)$ is the expected immediate reward with $k$ steps to go, conditioned on the belief and action with $t$ steps to go and assuming policy $\pi$ is followed after timestep $t$:

$$ G_k^G(b^k, a^k) = \gamma^{(h-k)} \sum_{z^k} Pr(z^{t:k}|b^k, a^k, \pi)(-H_{b^k}(s^k)). $$

where $z^{t:k}$ is a vector of observations received in the interval from $t$ steps to go to $k$ steps to go, $b^k$ is the belief at $t$ steps to go, $a^k$ is the action taken at $t$ steps to go, and $\rho(b^k) = -H_{b^k}(s^k)$, where $s^k$ is the state at $k$ steps to go.

Proving that $Q^G_t(b, a)$ is submodular in $\pi$ requires three steps. First, we show that $G_k^G(b^k, a^k)$ equals the conditional entropy of $b^k$ over $s^k$ given $z^{t:k}$. Second, we show that, under certain conditions, conditional entropy is a submodular set function. Third, we combine these two results to show that $Q^G_t(b, a)$ is submodular. The proofs of all following lemmas are detailed in the supplementary material.

**Lemma 2.** If $\rho(b) = -H_b(s)$, then the expected reward at each time step equals the negative discounted conditional entropy of $b^k$ over $s^k$ given $z^{t:k}$:

$$ G_k^G(b^k, a^k) = -\gamma^{(h-k)}(H_{b^k}(s^k|z^{t:k})) \forall \pi. \quad (23) $$

Next, we identify the conditions under which $G_k^G(b^k, a^k)$ is submodular in $a^k$. We use the set equivalent $\gamma$ of $z$ since submodularity is a property of set functions. Thus:

$$ G_k^G(b^k, a^k) = \gamma^{(h-k)}(-H_{b^k}(s|z^{t:k})). \quad (24) $$
where $\mathcal{z}^{t:k}$ is a set of observation features observed between $t$ and $k$ timesteps to go. The key condition required for submodularity of $G_k^{G}(b^t, a^t)$ is conditional independence (Krause and Guestrin 2007).

**Definition 1.** The observation set $\mathcal{z}$ is conditionally independent given $s$ if any pair of observation features are conditionally independent given the state, i.e.,

$$Pr(z_i, z_j|s) = Pr(z_i|s)Pr(z_j|s), \forall z_i, z_j \in \mathcal{z}. \quad (23)$$

**Lemma 3.** If $\mathcal{z}$ is conditionally independent given $s$ then $-H(s|\mathcal{z})$ is submodular in $\mathcal{z}$, i.e., for any two observations $\mathcal{z}_M$ and $\mathcal{z}_N$.

$$H(s|\mathcal{z}_M \cup \mathcal{z}_N) + H(s|\mathcal{z}_M \cap \mathcal{z}_N) \geq H(s|\mathcal{z}_M) + H(s|\mathcal{z}_N). \quad (24)$$

**Lemma 4.** If $\mathcal{z}^{t:k}$ is conditionally independent given $s^k$ and $\rho(b) = -H_b(s)$, then $G_k^{G}(b^t, a^t)$ is submodular in $a^t$.

Now we can establish the submodularity of $Q_t^{G}$.

**Theorem 3.** If $\mathcal{z}^{t:k}$ is conditionally independent given $s^k$ and $\rho(b) = -H_b(s)$, then $Q_t^{G}(b, a^t) = \rho(b) + \sum_{k=1}^{t} G_k^{G}(b^k, a^t)$ is submodular in $a^t$ for all $\pi$.

Proof. $\rho(b)$ is trivially submodular in $a$ because it is independent of $a$. Furthermore, Lemma 4 shows that $G_k^{G}(b^k, a^t)$ is submodular in $a^t$. Since a positively weighted sum of submodular functions is also submodular (Krause and Golovin 2014), this implies that $\sum_{k=1}^{t} G_k^{G}(b^k, a^t)$ and thus $Q_t^{G}(b, a^t)$ are also submodular in $a^t$.

While Theorem 3 shows that $Q_t^{G}(b, a)$ is submodular, Theorem 2 also requires that it be monotone, which we now establish.

**Lemma 5.** If $V_t^G$ is convex over the belief space for all $t$, then $Q_t^{G}(b, a)$ is monotone in $a$, i.e., for all $b$ and $a_M \subseteq a_N$, $Q_t^{G}(b, a_M) \leq Q_t^{G}(b, a_N)$.

Tying together our results so far:\n
**Theorem 4.** If $\mathcal{z}^{t:k}$ is conditionally independent given $s^k$, $V_t^G$ is convex over the belief space for all $t$, and $\rho(b) = -H_b(s)$, then for all $b$,

$$V_t^G(b) \geq (1 - e^{-1})^2 V_t^G(b). \quad (25)$$

Proof. Follows from Theorem 2, given $Q_t^{G}(b, a)$ is non-negative, monotone, and submodular. For $\rho(b) = -H_b(s)$, it is easy to see that $Q_t^{G}(b, a)$ is non-negative, as entropy is always positive (Cover and Thomas 1991). Theorem 3 showed that $Q_t^{G}(b, a)$ is submodular if $\rho(b) = -H_b(s)$. Lemma 5 shows that $Q_t^{G}(b, a)$ is monotone in $a$ if $V_t^G$ is convex.

**Analysis: Approximate Belief Entropy**

While Theorem 4 bounds the error in $V_t^G(b)$, it does so only on the condition that $\rho(b) = -H_b(s)$. However, as discussed earlier, our definition of a dynamic sensor selection POMDP instead defines $\rho$ using a set of vectors $\Gamma^\rho = \{\alpha_1^\rho, \ldots, \alpha_m^\rho\}$, each of which is a tangent to $-H_b(s)$, as suggested by (Araya et al. 2010), in order to preserve the PWLC property. While this can interfere with the submodularity of $Q_t^{G}(b, a)$, in this section we show that the error generated by this approximation is still bounded in this case.

Let $\hat{V}_t^*$ denote the optimal value function using a PWLC approximation to negative entropy for the belief-based reward, as in a dynamic sensor selection POMDP. Araya et al. (2010) showed that, if $\rho(b)$ verifies the $\alpha$-Hölder condition (Gilbarg and Trudinger 2001), a generalization of the Lipschitz condition, then the following relation holds between $V_t^*$ and $\hat{V}_t^*$:

$$||V_t^* - \hat{V}_t^*||_\infty \leq \frac{C\delta_B}{1 - \gamma}, \quad (26)$$

where $V_t^*$ is the optimal value function with $\rho(b) = -H_b(s)$, $\delta_B$ is a measure of how well belief entropy is approximated by the PWLC function, and $C$ is a constant.

Let $V_t^G(b)$ be the value function computed by greedy PBVI for the dynamic sensor selection POMDP.

**Lemma 6.** For all beliefs $b$, the error between $V_t^G(b)$ and $\hat{V}_t^*$ is bounded by $\frac{C\delta_B}{1 - \gamma}$. That is, $||V_t^G - \hat{V}_t^*||_1 \leq \frac{C\delta_B}{1 - \gamma}$.

Proof. Follows exactly the strategy Araya et al. (2010) used to prove (26), which places no conditions on $\pi$ and thus holds as long as $\mathcal{B}G$ is a contraction mapping. Since for any policy the Bellman operator $\mathcal{B}^\pi$ defined as:

$$(\mathcal{B}^\pi V_{t-1})(b) = [\rho(b, a_\pi) + \sum_{z \in \Omega} Pr(z|a_\pi, b) V_{t-1}(b^z, a_\pi)],$$

is a contraction mapping (Bertsekas 2007), the bound holds for $V_t^G$.

Let $\eta = \frac{C\delta_B}{1 - \gamma}$ and let $\hat{\rho}(b)$ denote the PWLC approximated belief-based reward and $\hat{Q}_t^{G}(b, a) = \hat{\rho}(b) + \sum_{z} Pr(z|b, a) \hat{V}_{t-1}^G(b^z, a)$ denote the value of taking action $a$ in belief $b$ under an optimal policy. Let $\hat{Q}_t^{G}(b, a)$ be the action-value function computed by greedy PBVI for the dynamic sensor selection POMDP. As mentioned before, it is not guaranteed that $\hat{Q}_t^{G}(b, a)$ is submodular. Instead, we show that it is $\epsilon$-submodular:

**Definition 2.** The set function $f(a)$ is $\epsilon$-submodular in $a$, if for every $a_M \subseteq a_N \subseteq A^+$, $a_{\epsilon} \in A^+ \setminus a_N$ and $\epsilon \geq 0$,

$$f(a_M) - f(a_M) \geq f(a_{\epsilon}) - f(a_N) - \epsilon.$$

**Lemma 7.** If $||V_{t-1}^G - \hat{V}_{t-1}^G||_1 \leq \eta$, and $Q_t^{G}(b, a)$ is submodular in $a$, then $Q_t^{G}(b, a)$ is $\epsilon'$-submodular in $a$ for all $b$, where $\epsilon' = 4(\gamma + 1)\eta$.

**Lemma 8.** If $Q_t^{G}(b, a)$ is non-negative, monotone and $\epsilon$-submodular in $a$, then

$$\hat{Q}_t^{G}(b, a^G) \geq (1 - e^{-\gamma}) \hat{Q}_t^{G}(b, a^G) - 4\chi_K \epsilon, \quad (28)$$

where $\chi_K = \sum_{p=0}^{K-1} (1 - K^{-1})^p$. 

---

\(^1\)This is the latest (and corrected) version of this paper. Lemma 6 in the old version was found to be incorrect. We thank Csaba Szepesvári for pointing that.
Theorem 5. For all beliefs, the error between $V_t^G(b)$ and $\tilde{V}_t^G(b)$ is bounded, if $\rho(b) = -H_b(s)$, $V_t^\pi$ is convex over the belief space for all $t$, $\pi$, and $z^{t:k}$ is conditionally independent given $s^k$.

Proof. Theorem 4 shows that, if $\rho(b) = -H_b(s)$, and $z^{t:k}$ is conditionally independent given $s^k$, then $Q^G_t(b,a)$ is submodular. Using Lemma 7, for $V_t^G = V_t^G$, $\tilde{V}_t^G = \tilde{V}_t^G$, $Q_t^G(b,a) = Q_t^G(b,a)$ and $\tilde{Q}_t^G(b,a) = \tilde{Q}_t^G(b,a)$, it is easy to see that $\tilde{Q}_t^G(b,a)$ is $\epsilon$-submodular. This satisfies one of the conditions of Lemma 8. Given that $\tilde{V}_t^G(b)$ is convex, the monotonicity of $\tilde{Q}_t^G(b,a)$ follows from Lemma 5. Since $\tilde{\rho}(b)$ is non-negative, $\tilde{Q}_t^G(b,a)$ is non-negative too. Thus, now we can apply Lemma 9 to prove that the error generated by a one-time application of the greedy Bellman operator to $\tilde{V}_t^G(b)$, instead of the Bellman optimality operator, is bounded. It is thus easy to see that the error between $\tilde{V}_t^G(b)$, produced by multiple applications of the greedy Bellman operator, and $V_t^G(b)$ is bounded for all beliefs. □

Experiments

To empirically evaluate greedy PBVI, we tested it on the problem of tracking either one or multiple people using a multi-camera system. The problem was extracted from a real-world dataset collected in a shopping mall (Bouma et al. 2013). The dataset was gathered over 4 hours using 13 CCTV cameras located in a shopping mall. Each camera uses a FPDD pedestrian detector (Dollár, Belongie, and Perona 2010) to detect people in each camera image and in-camera tracking (Bouma et al. 2013) to generate tracks of the detected people’s movement over time. The dataset thus consists of 9915 tracks, each specifying one person’s $x$-$y$ position throughout time. Figure 2 shows sample tracks from all of the cameras.

To addressing increasing size of state space for multi-person tracking, we use a variant of transfer planning as proposed in (Oliehoek, Whiteson, and Spaan 2013). We divide the multi-person problem into a number of source problem, one for each person and solve them independently to compute $V_t(b) = \sum V^i(b_i)$, where $V^i(b_i)$ is the value of the current belief $b_i$ about the $i$-th person’s location. Thus $V_t^G(b_i)$ only needs to be computed once, by solving POMDP of the same size as that in the single-person setting. During action selection, $V_t^G(b_i)$ is computed using the current $b_i$ for each person.

As baselines, we tested against regular PBVI as well as myopic versions of both greedy and regular PBVI that compute a policy assuming $\hat{h} = 1$ and use it at each timestep. More details about the experiments can be found in the extended version(Satsangi, Whiteson, and Oliehoek 2014) of the paper.

Figure 3, which shows runtimes under different values of $N$ and $K$, demonstrates that greedy PBVI requires only a fraction of the computational cost. Since, we use the value function obtained by solving POMDP for single-person, for multi-person tracking, single and multi-person tracking have the same runtimes. In addition, the difference in runtime grows quickly as the action space gets larger: for $N = 5$ and $K = 11$, greedy PBVI is twice as fast, while for $N = 11$, $K = 3$ it is approximately nine times as fast. Thus, greedy PBVI enables much better scalability in the action space.

Figure 4, which shows the cumulative reward under different values of $N$ and $K$ for single-person (top) and multi-person (bottom) tracking, verifies that greedy PBVI’s speedup does not come at the expense of performance, as greedy PBVI accumulates nearly as much reward as regular PBVI. They also show that both PBVI and greedy PBVI benefit from non-myopic planning. While the performance advantage of non-myopic planning is relatively modest, it increases with the number of cameras and people, which suggests that non-myopic planning is important to making active perception scalable.

Furthermore, an analysis of the resulting policies showed that myopic and non-myopic policies differ qualitatively. A myopic policy, in order to minimise uncertainty in the next step, tends to look where it believes the person to be. By contrast, a non-myopic policy tends to proactively look where the person might go next, so as to more quickly detect her new location when she moves. Consequently, non-myopic policies exhibit less fluctuation in belief and accumulate more reward, as illustrated in Figure 5. The blue lines mark when the agent chose to observe the cell occupied by the person and the red line plots the max of the agent’s belief. The difference in fluctuation in belief is evident from the figure as the max of the belief often drops below 0.5 for the myopic policy, but rarely for the non-myopic policy.
**Related Work**

Dynamic sensor selection has been studied in many contexts. Most work focuses on either open-loop or myopic solutions, e.g., (Kreucher, Kastella, and Hero 2005; Williams, Fisher, and Willsky 2007; Joshi and Boyd 2009). By contrast, our POMDP-approach enables a closed-loop, non-myopic approach that can lead to better performance when the underlying state of the world changes over time.

Spaan (2008) and Spaan and Lima (2009) also consider a POMDP approach to dynamic sensor selection. However, they apply their method only to small POMDPs without addressing scalability with respect to the action space. Such scalability, which greedy PBVI makes possible, is central to the practical utility of POMDPs for sensor selection. Other work using POMDPs for sensor selection (Krishnamurthy and Djonin 2007; Ji, Parr, and Carin 2007) also does not consider scalability in the action space. Krishnamurthy and Djonin (2007) consider a non-standard POMDP in which, unlike in our setting, the reward is not linear in the belief.

In recent years, applying greedy maximization to submodular functions has become a popular and effective approach to sensor selection (Krause and Guestrin 2005; 2007). However, such work focuses on myopic or fully observable settings (Kumar and Zilberstein 2009) and thus does not enable the long-term planning required to cope with dynamic state in a POMDP.

Adaptive submodularity (Golovin and Krause 2011) is a recently developed extension that addresses these limitations by allowing action selection to condition on previous observations. However, it assumes a static state and thus cannot model the dynamics of POMDP across timesteps. Therefore, in a POMDP, adaptive submodularity is only applicable within a timestep, during which state does not change but the agent can sequentially add sensors to a set. In principle, adaptive submodularity could enable this intra-timestep sequential process to be adaptive, i.e., the choice of later sensors could condition on the observation generated by earlier sensors. However, this is not possible in our setting because we assume that, due to computational costs, all sensors must be selected simultaneously. Consequently, our analysis considers only classic, non-adaptive submodularity.

To our knowledge, our work is the first to establish the submodularity of POMDP value functions for dynamic sensor selection POMDPs and thus leverage greedy maximization to scalably compute bounded approximate policies for dynamic sensor selection modeled as a full POMDP.

**Conclusions & Future Work**

This paper proposed greedy PBVI, a new POMDP planning method for dynamic sensor selection that exploits greedy maximization to improve scalability in the action space. We showed that the value function computed in this way has bounded error if certain conditions including submodularity are met. We also showed that such conditions are met, or approximately met, if reward is defined using negative belief entropy or an approximation thereof. Experiments on a real-world dataset from a multi-camera tracking system show that it achieves similar performance to existing methods but incurs only a fraction of the computational cost, leading to much better scalability in the number of cameras.

One avenue for future work includes quantifying the error bound between $\bar{V}^G_t(b)$ and $V^*_t(b)$, as our current results (Theorem 5) show only that it is bounded. Another avenue is to develop on-line POMDP planning methods that exploit...
submodularity by employing greedy maximization. We also intend to consider cases where its possible to sequentially process information from sensors and thus integrate our approach with adaptive submodularity.
